Perform simple and accurate Hankel transformations using the method of Ogata 2005.

Hankel transforms and integrals are commonplace in any area in which Fourier Transforms are required over fields that are radially symmetric (see Wikipedia for a thorough description). They involve integrating an arbitrary function multiplied by a Bessel function of arbitrary order (of the first kind). Typical integration schemes often fail because of the highly oscillatory nature of the transform. Ogata's quadrature method used in this package provides a fast and accurate way of performing the integration based on locating the zeros of the Bessel function.

ONE

FEATURES

- Accurate and fast solutions to many Hankel integrals
- Easy to use and re-use
- Arbitrary order transforms
- Built-in support for radially symmetric Fourier Transforms
- Thoroughly tested.
- only Python 3 compatible.

TWO

QUICK LINKS

- Documentation: https://hankel.readthedocs.io
- Quickstart+Description: Getting Started

THREE

INSTALLATION

Either clone the repository and install locally (best for developer installs):

```
$ git clone https://github.com/steven-murray/hankel.git
$ cd hankel/
$ pip install -U .
```

Or install from PyPI:

```
$ pip install hankel
```

Or install with conda:

```
$ conda install -c conda-forge hankel
```

The only dependencies are numpy, scipy and mpmath. These will be installed automatically if they are not already installed.

Dependencies required purely for development (testing and linting etc.) can be installed via the optional extra *pip install hankel[dev]*. If using *conda*, they can still be installed via *pip*: *pip install -r requirements_dev.txt*.

For instructions on testing *hankel* or any other development- or contribution-related issues, see the contributing guide.

FOUR

ACKNOWLEDGING

If you find *hankel* useful in your research, please cite

SIX

CONTENTS

6.1 Examples

To help get you started using hankel, we've compiled a few extended examples. Other simple examples can be found in the API documentation for each object, or by looking at some of the tests.

6.1.1 Getting Started with Hankel

Usage and Description

h = 0.03

)

Setup

This implementation is set up to allow efficient calculation of multiple functions f(x). To do this, the format is classbased, with the main object taking as arguments the order of the Bessel function, and the number and size of the integration steps (see *Limitations* for discussion about how to choose these key parameters).

For any general integration or transform of a function, we perform the following setup:

Proxy for "size" of steps in integration

```
[1]: import hankel
from hankel import HankelTransform  # Import the basic class
print("Using hankel v{}".format(hankel.__version__))
Using hankel v0.3.7
[2]: ht = HankelTransform(
    nu= 0,  # The order of the bessel function
    N = 120,  # Number of steps in the integration
```

Alternatively, each of the parameters has defaults, so you needn't pass any. The order of the bessel function will be defined by the problem at hand, while the other arguments typically require some exploration to set them optimally.

Integration

A Hankel-type integral is the integral

$$\int_0^\infty f(x) J_\nu(x) dx.$$

Having set up our transform with nu = 0, we may wish to perform this integral for f(x) = 1. To do this, we do the following:

```
[3]: # Create a function which is identically 1.
    f = lambda x : 1
    ht.integrate(f)
[3]: (1.00000000003486, -9.838142836853752e-15)
```

The correct answer is 1, so we have done quite well. The second element of the returned result is an estimate of the error (it is the last term in the summation). The error estimate can be omitted using the argument ret_err=False.

We may now wish to integrate a different function, say $x/(x^2 + 1)$. We can do this directly with the same object, without re-instantiating (avoiding unnecessary recalculation):

```
[4]: f = lambda x : x/(x**2 + 1)
ht.integrate(f)
[4]: (0.42098875721567186, -2.6150757700135774e-17)
```

The analytic answer here is $K_0(1) = 0.4210$. The accuracy could be increased by creating ht with a higher number of steps N, and lower stepsize h (see *Limitations*).

Transforms

The Hankel transform is defined as

$$F_{\nu}(k) = \int_0^\infty f(r) J_{\nu}(kr) r dr.$$

We see that the Hankel-type integral is the Hankel transform of f(r)/r with k = 1. To perform this more general transform, we must supply the k values. Again, let's use our previous function, $x/(x^2 + 1)$.

First we'll import some libraries to help us visualise:

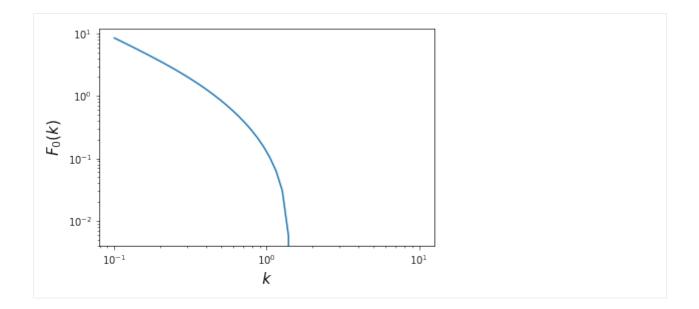

```
[5]: import numpy as np  # Import numpy
import matplotlib.pyplot as plt
%matplotlib inline
```

Now do the transform,

```
[6]: k = np.logspace(-1,1,50)  # Create a log-spaced array of k from 0.1 to 10.
Fk = ht.transform(f,k,ret_err=False) # Return the transform of f at k.
```

and finally plot it:

```
[8]: plt.plot(k,Fk)
   plt.xscale('log')
   plt.yscale('log')
   plt.ylabel(r"$F_0(k)$", fontsize=15)
   plt.xlabel(r"$k$", fontsize=15)
   plt.show()
```

Fourier Transforms

One of the most common applications of the Hankel transform is to solve the radially symmetric n-dimensional Fourier transform:

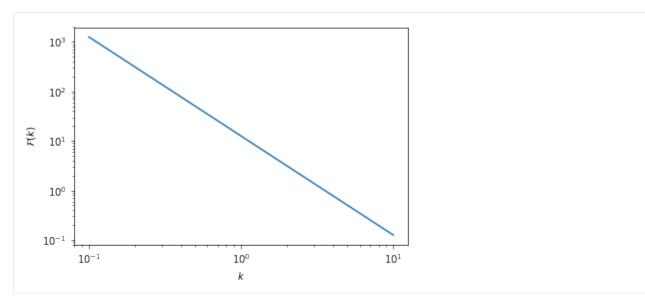

$$F(k) = \frac{(2\pi)^{n/2}}{k^{n/2-1}} \int_0^\infty r^{n/2-1} f(r) J_{n/2-1}(kr) r dr.$$

We provide a specific class to do this transform, which takes into account the various normalisations and substitutions required, and also provides the inverse transform. The procedure is similar to the basic HankelTransform, but we provide the number of dimensions, rather than the Bessel order directly.

Say we wish to find the Fourier transform of f(r) = 1/r in 3 dimensions:

```
[9]: # Import the Symmetric Fourier Transform class
from hankel import SymmetricFourierTransform
# Create our transform object, similar to HankelTransform,
# but with ndim specified instead of nu.
ft = SymmetricFourierTransform(ndim=3, N = 200, h = 0.03)
# Create our kernel function to be transformed.
f = lambda r : 1./r
# Perform the transform
Fk = ft.transform(f,k, ret_err=False)
```

```
[10]: plt.plot(k,Fk)
   plt.xscale('log')
   plt.yscale('log')
   plt.ylabel(r"$\mathcal{F}(k)$")
   plt.xlabel(r"$k$")
   plt.show()
```

To do the inverse transformation (which is different by a normalisation constant), merely supply inverse=True to the .transform() method.

Limitations

Efficiency

An implementation-specific limitation is that the method is not perfectly efficient in all cases. Care has been taken to make it efficient in the general sense. However, for specific orders and functions, simplifications may be made which reduce the number of trigonometric functions evaluated. For instance, for a zeroth-order spherical transform, the weights are analytically always identically 1.

Lower-Bound Convergence

Theoretically, since Bessel functions have asymptotic power-law slope of n/2 - 1 as $r \to 0$, the function f(r) must have an asymptotic slope > -n/2 in this regime in order to converge. This restriction is method-independent.

In terms of limitations of the method, they are very dependent on the form of the function chosen. Notably, functions which either have sharp features at low r, or tend towards a slope of $\sim -n/2$, will be poorly approximated in this method, and will be highly dependent on the step-size parameter, as the information at low-x will be lost between 0 and the first step. As an example consider the simple function $f(x) = 1/\sqrt{x}$ with a 1/2 order bessel function. The total integrand tends to 1 at x = 0, rather than 0:

```
[11]: f = lambda x: 1/np.sqrt(x)
h = HankelTransform(0.5,120,0.03)
h.integrate(f)
```

[11]: (1.2336282257874065, -2.864861354876958e-16)

The true answer is $\sqrt{\pi/2}$, which is a difference of about 1.6%. Modifying the step size and number of steps to gain accuracy we find:

```
[12]: h = HankelTransform(0.5,700,0.001)
h.integrate(f)
```

[12]: (1.2523045155005623, -0.0012281146007915768)

This has much better than percent accuracy, but uses 5 times the amount of steps. The key here is the reduction of h to "get inside" the low-x information.

Upper-Bound Convergence

Theoretically, since the Bessel functions decay as $r^{-1/2} \cos r$ as $f \to \infty$, the asymptotic logarithmic slope of f(r) must be < (1 - n)/2 in order to converge.

As the asymptotic slope approaches this value, higher and higher zeros of the Bessel function will be required to capture the convergence. Often, it will be the case that if this is so, the amplitude of the function is low at low x, so that the step-size h can be increased to facilitate this. Otherwise, the number of steps N can be increased.

For example, the 1/2-order integral supports functions that are increasing up to $f(x) = x^{0.5}$. Let's use $f(x) = x^{0.4}$ as an example of a slowly converging function, and use our "hi-res" setup from the previous section. We note that the analytic result is 0.8421449.

```
[20]: f = lambda x : x**0.4
```

```
[25]: %%timeit
```

```
HankelTransform(0.5,700,0.001).integrate(f)
```

```
735 \mus ± 8.11 \mus per loop (mean ± std. dev. of 7 runs, 1000 loops each)
```

```
[26]: res = HankelTransform(0.5,700,0.001).integrate(f)
print("Relative Error is: ", res[0]/0.8421449 - 1)
print("Predicted Abs. Error is: ", res[1])
Relative Error is: -0.362600451237186
Predicted Abs. Error is: -1.05909546212511
```

Our result is way off. Note that in this case, the error estimate itself is a good indication that we haven't reached convergence. We could try increasing N:

```
[27]: h = HankelTransform(0.5,10000,0.001)
print("Relative Error is: ", h.integrate(f,ret_err=False)/0.8421449 -1)
Relative Error is: 7.133537831549575e-07
```

This is very accurate, but quite slow:

```
[28]: %%timeit
HankelTransform(0.5,10000,0.001).integrate(f)
9.12 ms ± 211 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
```

Alternatively, we could try increasing h:

```
[18]: h = HankelTransform(0.5,700,0.03)
h.integrate(f,ret_err=False)/0.8421449 -1
```

```
[18]: 0.00045613842025526985
```

Not quite as accurate, but still far better than a percent for a tenth of the cost:

[29]: %%timeit

HankelTransform(0.5,700,0.03).integrate(f) 718 μ s ± 2.04 μ s per loop (mean ± std. dev. of 7 runs, 1000 loops each)

We explore how to determine N and h in more detail in another demo, and hankel provides the get_h function to automatically determine these values (at some computational cost).

6.1.2 Testing Forward and Inverse Hankel Transform

This is a simple demo to show how to compute the forward and inverse Hankel transform, essentially returning to the original function.

This is a common application, where often the transformed function is modified before performing the inverse transform (eg. in the calculation of a Laplacian). However, it is not explicitly supported by hankel, since the transformed function itself is merely encoded as a set of values, rather than a callable function. This demo shows the simplest route to closing this gap, using splines. It also highlights some of the issues one may encounter along the way.

This application is also important, as it is able to self-consistently test the accuracy of the transformation for any arbitrary function f(r). The returned function should be very close to this function for an accurate transform. This idea is explored further in the demo on choosing resolution parameters.

We use the function $f(r) = 1/(r^2 + 1)$ as an example function.

```
[1]: # Import libraries
```

```
[53]: # Define grid
```

```
r = np.linspace(0,1,100)[1:]  # Define a physical grid
k = np.logspace(-3,2,100)  # Define a spectral grid
```

[54]: # Compute Forward Hankel transform

```
f = lambda r : 1/(r**2 + 1)  # Sample Function
h = HankelTransform(nu=0,N=1000,h=0.005)  # Create the HankelTransform_
→instance, order zero
hhat = h.transform(f,k,ret_err=False)  # Return the transform of f at k.
```

[55]: # Compute Inverse Hankel transform

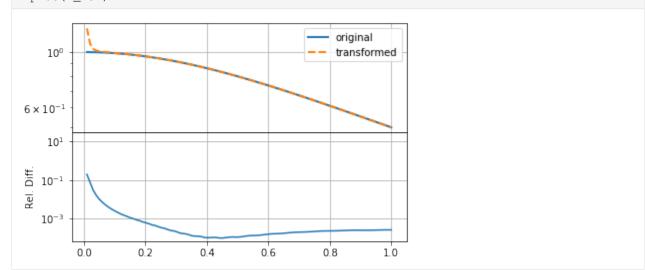

```
hhat_sp = spline(k, hhat)  # Define a spline to_

→ approximate transform

f_new = h.transform(hhat_sp, r, False, inverse=True) # Compute the inverse transform
```

```
[56]: def mkplot(f_new):
    fig,ax = plt.subplots(2,1,sharex=True,gridspec_kw={"hspace":0})
    ax[0].semilogy(r,f(r), linewidth=2,label='original')
    ax[0].semilogy(r,f_new,ls='--',linewidth=2,label='transformed')
    ax[0].grid(True)
    ax[0].legend(loc='best')
    ax[1].plot(r,np.abs(f(r)/f_new-1))
    ax[1].set_yscale('log')
    ax[1].set_ylim(None,30)
    ax[1].grid(True)
    ax[1].set_ylabel("Rel. Diff.")
    plt.show()
```

The result here is reasonable, though not very accurate, especially at small r.

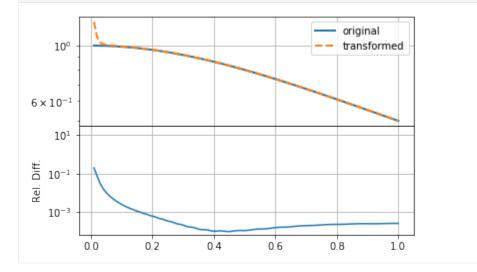

In practice, there are three aspects that affect the accuracy of the round-trip transformed function, other than the features of the function itself:

- 1. the value of N, which controls the the upper limit of the integral (and must be high enough for convergence),
- 2. the value of h, which controls the resolution of the array used to do integration. Most importantly, controls the position of the *first sample* of the integrand. In a function such as 1/r, or something steeper, this must be small to capture the large amount of information at low r.
- 3. the resolution/range of k, which is used to define the function which is inverse-transformed.

As a simple empirical exercise, we modify each of these three below to estimate their importance in this particular transform (see the demo on choosing resolution parameters for a more thorough investigation):

Changing N

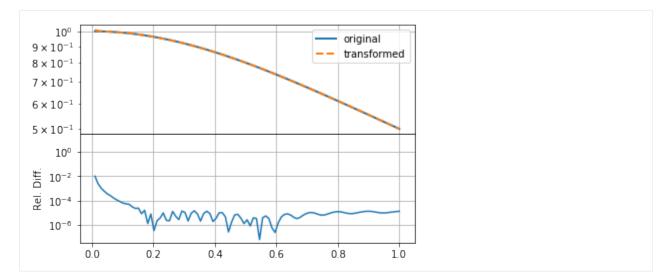

```
[60]: mkplot(f_new)
```

Increasing N in this case does not seem to make the solution any better.

Changing h

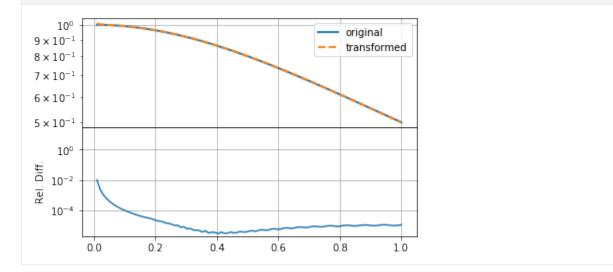

```
[62]: mkplot(f_new)
```

Clearly changing h makes much more of a difference, reducing the relative error by an order of magnitude. In this case, we ensured that the product hN remained the same (as the original example), so that the upper bound on the summation remained approximately the same. This indicates that either f(r) or F(k) has high-resolution information.

Changing k

[64]: mkplot(f_new)

Having set k to extend to smaller scales, as well as increasing its resolution, has not helped the accuracy of the transformation, though it does seemed to have smoothed out small-scale wiggles in the transformation. Thus we

can see that the predominant problem in this case was that the integration grid was not fine enough to capture the small-scale information in the function (either f(r) or F(k)).

Any procedure like this will have to explore the values of these three parameters in order to set them as efficiently and accurately as possible.

6.1.3 Choosing Resolution Parameters

The only real choices to be made when using hankel are the choice of resolution parameters N and h. Roughly speaking, h controls the quadrature bin width, while N controls the number of these bins, ideally simulating infinity. Here we identify some rules of thumb for choosing these parameters so that desired precision can be attained.

For ease of reference, we state our problem explicitly. We'll deal first with the simple Hankel integral, moving onto a transformation, and Symmetric FT in later sections. For an input function f(x), and transform of order ν , we are required to solve the Hankel integral

$$\int_0^\infty f(x) J_\nu(x) dr. \tag{6.1}$$

The O5 method approximates the integral as

$$\hat{f}(K) = \pi \sum_{k=1}^{N} w_{\nu k} f(y_{\nu k}) J_{\nu}(y_{\nu k}) \psi'(hr_{\nu k}),$$
(6.2)

where

$$y_{\nu k} = \pi \psi(h r_{\nu k})/h \tag{6.3}$$

$$\psi(t) = t \tanh(\pi \sinh(t)/2) \tag{6.4}$$

$$\psi'(t) = \frac{\pi t \cosh(t) + \sinh(\pi \sinh(t))}{1 + \cosh(\pi \sinh(t))}$$
(6.5)

$$w_{\nu k} = \frac{Y_{\nu}(\pi r_{\nu k})}{J_{\nu+1}(\pi r_{\nu k})}.$$
(6.6)

Here $Y_{\nu}(x)$ is a Bessel function of the second kind, and $r_{\nu k}$ are the roots of $J_{\nu}(\pi r)$.

Simple Hankel Integral

Choosing N given h

Choosing a good value of N given h is a reasonably simple task. The benefit of the O5 method is that the successive nodes approach the roots of the Bessel function double-exponentially. This means that at some term k in the series, the Bessel function term in the sum approaches zero, and for reasonably low k.

This is because for large t, $\psi(t) \approx t$, so that $y_{\nu k} \approx \pi r_{\nu k}$, which are the roots (r are the roots scaled by π). Thus we can expect that a plot of the values of $J_{\nu}(y_{\nu k})$ should fall to zero, and they should do this approximately identically as a function of $hr_{\nu k}$.

```
[1]: from scipy.special import yv, jv
from scipy.integrate import simps
from mpmath import fp as mpm
import numpy as np
import matplotlib.pyplot as plt
import matplotlib as mpl
%matplotlib inline
```

(continues on next page)

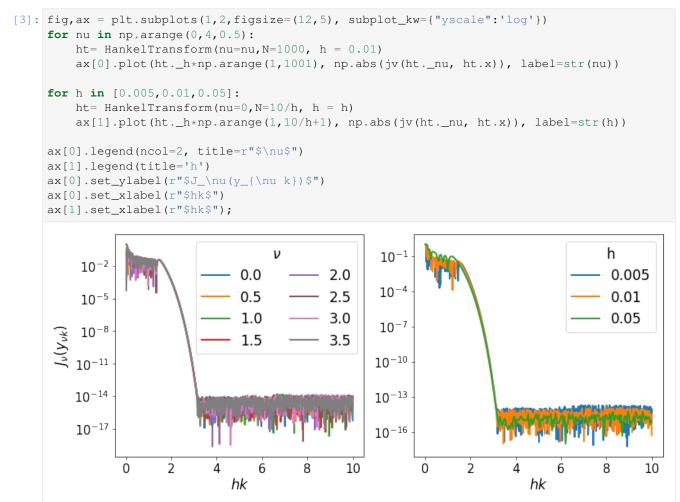

(continued from previous page)

```
%load_ext autoreload
%autoreload 2
from hankel import HankelTransform, SymmetricFourierTransform
import hankel
print("Using hankel v{}".format(hankel.__version__))
```

Using hankel v0.3.7

```
[2]: mpl.rcParams['lines.linewidth'] = 2
mpl.rcParams['xtick.labelsize'] = 15
mpl.rcParams['ytick.labelsize'] = 15
mpl.rcParams['font.size'] = 17
mpl.rcParams['axes.titlesize'] = 14
```

We test our assertion by plotting these values for a range of ν and h:

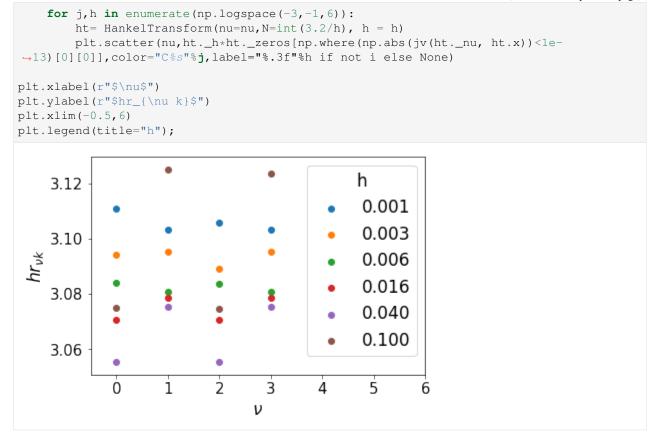

Interestingly, the fall-off is very similar across a range of both ν and h. We can compute where approximately the fall-off is completed:

```
[4]: for i,nu in enumerate( np.arange(0,4)):
```

(continues on next page)

(continued from previous page)

Now, let's assume that N is reasonably large, so that the Bessel function is close to its asymptotic limit, in which

$$r_{\nu k} = k - \frac{\pi \nu}{2} - \frac{\pi}{4} \approx k.$$
 (6.7)

Then we merely set $hr_{\nu k} = hN = 3.2$, i.e. $N = \pi/h$.

It may be a reasonable question to ask whether we could set N significantly lower than this limit. The function f(x) may converge faster than the Bessel function itself, in which case the limit could be reduced. In this regard it is useful to keep in mind that the sum extends to $r \sim \pi N$, if N is reasonably large. If f(x) falls to zero for $x \ll \pi^2/h$, then it is probably reasonable to use a lower value of N.

However, for simplicity, for the rest of our analysis, we consider N to be set by this relation, and change h to modify N.

Choosing h

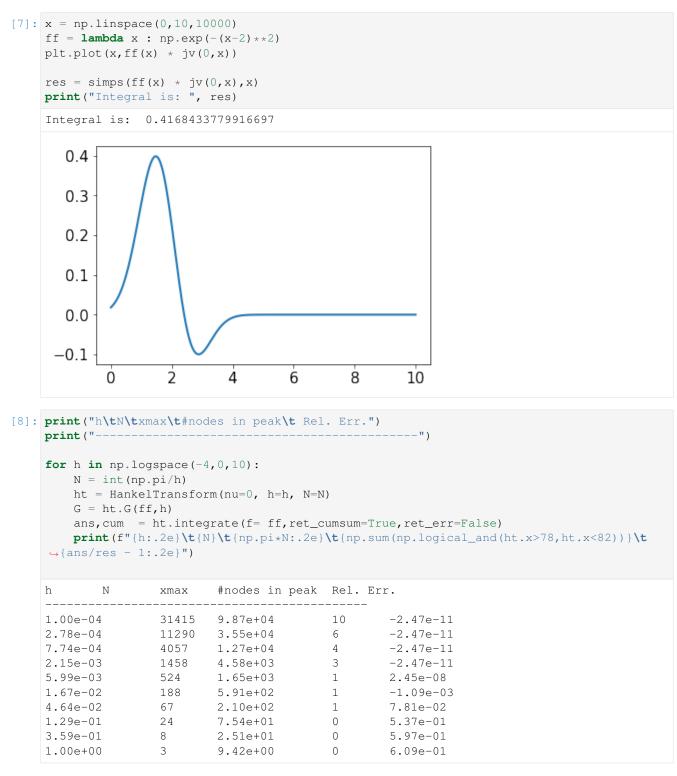

O5 give a rather involved proof of an upper limit on the residual error of their method as a function of h. Unfortunately, evaluating the upper limit is non-trivial, and we pursue a more tractable approach here, namely iteratively modifying h until convergence is reached.

As an example, let's take a sharp Gaussian, $f(x) = e^{-(x-80)^2}$ with $\nu = 0$:

In the above example we see that only for very large values of h was the criteria of negative derivative not met. However, the criteria of covering the interesting region with nodes was only met by the smallest 5 values of h, each of which yields a good value of the integral.

Doing the same example, but moving the Gaussian closer to zero yields a different answer:

Here we are able to achieve good precision with just ~500 terms.

These ideas are built into the get_h function in hankel. In particular, this function progressively iterates through a series of values for h, and stops when two consecutive results are within a certain tolerance of each other. On each iteration, it uses $N = \pi/h$.

While this function is not entirely general – there are cases in which the algorithm will return prematurely – it should

do well in cases where the integrand is reasonably smooth. In addition to the convergence of the result, it also checks that the derivative of G is decreasing. Furthermore, it truncates N if possible such that $f(x_k) = 0 \quad \forall k > N$.

An example:

```
[9]: best_h, result, best_N = hankel.get_h(
    f =lambda x : np.exp(-(x-2)**2),
    nu=0
)
print(f"best_h = {best_h}, best_N={best_N}")
print("Relative Error: ", result/res - 1)
best_h = 0.0125, best_N=22
Relative Error: -0.00011951202608917466
```

Here we can see that while a low value of h was required, a corresponding high value of N was not, as the function itself converges quickly.

We can also repeat our previous experiment where a sharp Gaussian sits at high x:

```
[10]: best_h, result, best_N = hankel.get_h(
    f =lambda x : np.exp(-(x-80.)**2),
    nu =0
)
print(f"best_h = {best_h}, best_N={best_N}")
print("Relative Error: ", result/res80 - 1)
best_h = 0.00078125, best_N=168
Relative Error: 0.002185348402481635
```

Here both a lower h and higher N are required, but again, N does not need to be as large as π/h .

We can modify the required tolerance:

```
[11]: best_h, result, best_N = hankel.get_h(
    f =lambda x : np.exp(-(x-2)**2),
    nu=0,
    atol=1e-10,
    rtol=1e-15
)
print(f"best_h = {best_h}, best_N={best_N}")
print("Relative Error: ", result/res - 1)
best_h = 0.003125, best_N=44
Relative Error: -2.470723625691562e-11
```

Remember that the tolerances submitted to the get_h function apply to the similarity between successive iterations. The relative error displayed here may be dominated by numerical error on the simpson's integration.

Finally we try a different kind of function, namely one that converges slowly:

```
[12]: best_h, result, best_N = hankel.get_h(
    f =lambda x : x**0.4,
    nu=0.5,
    atol=1e-5,
    rtol=1e-5
)
print(f"best_h = {best_h}, best_N={best_N} (max is {int(np.pi/best_h)})")
print("Relative Error: ", result/0.8421449 - 1)
```

best_h = 0.00625, best_N=502 (max is 502) Relative Error: 2.317849153432583e-05

In this case, the required N is the maximum required, as we need to integrate quite far in order to converge.

Symmetric Fourier Transform

In the context of the symmetric Fourier Transform, much of the work is exactly the same – the relationship between N and h necessarily remains. The only differences are that we now use the SymmetricFourierTransform class instead of the HankelTransform (and pass ndim rather than nu), and that we are now interested in the *transform*, rather than the integral, so we have a particular set of scales, K, in mind.

For a given K, the minimum and maximum values of x that we evaluate f(x) for are $x_{\min} \approx \pi^2 h r_{\nu 1}^2 / 2K$ and $x_{\max} \approx \pi N/K$. We suggest find a value h that works for both the minimum and maximum K desired. All scales in between should work in this case.

We have already written this functionality into the get_h function. However, here nu is interpreted directly as n, and we need to pass a value for K.

```
[13]: hankel.get_h(
    f = lambda x : np.exp(-x**2), nu=2,
    K= np.array([0.01, 100]),
    cls=SymmetricFourierTransform
)
[13]: (0.05, array([8.25274593e-88, 1.38996118e-09]), 62)
```

6.1.4 Computing Laplacian Transforms with Hankel vs FFT

This will compare the forward and inverse transforms for both Hankel and Fourier by either computing partial derivatives of solving a parital differential equation. This notebook focuses on the Laplacian operator in the case of radial symmetry.

Consider two 2D circularly-symmetric functions f(r) and g(r) that are related by the following differential operator,

$$g(r) = \nabla^2 f(r) = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial f}{\partial r} \right)$$

In this notebook we will consider four problems: 1. Given f(r), compute the Laplacian to obtain g(r) 2. Given g(r), invert the Laplacian to obtain f(r) 3. Repeat step 1., but under the assumption that f(r) is defined in 3D. 4. Repeat step 1., but for *n*-dimensional f(r).

For our fiducial 2D case, we can use the 1D Hankel (or 2D Fourier) transform to compute the Laplacian in three steps:

1. Compute the Forward Transform

$$\mathcal{H}[f(r)] = \hat{f}(k)$$

2. Differentiate in Spectral space

$$\hat{g}(k) = -k^2 \hat{f}(k)$$

\$

3. Compute the Inverse Transform

$$g(r) = \mathcal{H}^{-1}[\hat{g}(k)]$$

In particular, we will use the function

$$f(r) = e^{-r^2},$$

and, though it is arbitrary, we will use the Fourier convention that (a, b) = (1, 1) (i.e. $F(k) = \int dr f(r)e^{-ik \cdot r}$). This gives the corollary functions

$$\hat{f}(k) = \pi e^{-k^2/4}$$
$$\hat{g}(k) = -k^2 \pi e^{-k^2/4}$$
$$g(r) = 4e^{-r^2}(r^2 - 1)$$

This is easily done in two-dimensions using the Fast Fourier Transform (FFT) but one advantage of the Hankel transform is that we only have a one-dimensional transform. The purpose of this notebook is twofold:

- 1. To show how one would solve the n-dimensional Laplacian numerically using Hankel transforms
- 2. To compare the performance and accuracy of the Hankel-based approach and an FFT-based approach to the solutions.

We shall see that over a suitable range of scales, and for low number of dimensions n, the FFT approach is more accurate than the Hankel approach, due to the fact that its forward-then-inverse operation is an identity operation by construction (whereas the numerical Hankel routine loses information in both directions). Nevertheless, the Hankel method, without much tuning, is shown to be accurate to 10^{-5} over many of the useful scales. Furthermore, as the dimensionality grows, the Hankel transform becomes the only viable option computationally.

Setup

Import Relevant Libraries

```
[3]: # Import Libraries
                                                                                   # Numpy
    import numpy as np
    from powerbox import dft
                                                                                   # powerbox_
     \rightarrow for DFTs (v0.6.0+)
                                                                                   # Hankel
    from hankel import SymmetricFourierTransform
    from scipy.interpolate import InterpolatedUnivariateSpline as spline
                                                                                  # Splines
    import matplotlib.pyplot as plt
                                                                                   # Plotting
     %matplotlib inline
    import hankel
    print("Using hankel v{}".format(hankel.__version__))
    Using hankel v0.3.8
```

Define Sample Functions

```
[4]: f = lambda r: np.exp(-r**2)
g = lambda r: 4.0*np.exp(-r**2)*(r**2 - 1.0)
fhat = lambda k : np.pi * np.exp(-k**2/4)
ghat = lambda k : -k**2 * np.pi * np.exp(-k**2/4)
```

Define Transformation Functions

```
[15]: def ft2d(X, L, inverse=False):
    """Convenience function for getting nD Fourier Transform and a 1D function of it""
    if inverse:
        ft, _, xgrid = dft.ifft(X, L=L, a=1, b=1, ret_cubegrid=True)
    else:
        ft, _, xgrid = dft.fft(X, L=L, a=1, b=1, ret_cubegrid=True)
    # Get a sorted array of the transform
    ind = np.argsort(xgrid.flatten())
    _xgrid = xgrid.flatten()[ind]
    _ft = ft.flatten()[ind]
    # Just take unique values.
    _xgrid, ind = np.unique(_xgrid, return_index=True)
    _ft = _ft[ind]
    return ft, xgrid, _xgrid, _ft.real # we only deal with real functions here.
```

Grid Setup

```
[4]: L = 10.0 # Size of box for transform
N = 128 # Grid size
b0 = 1.0
```

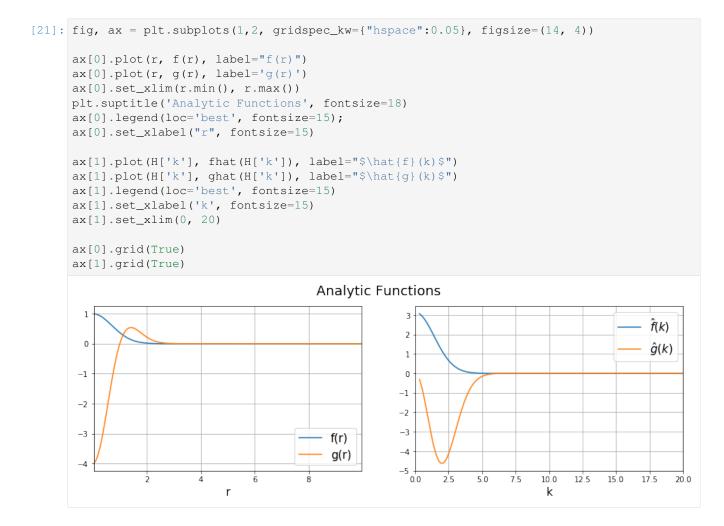

[77]: # Create the Hankel Transform object

```
ht = SymmetricFourierTransform(ndim=2, h=0.005)
```

```
[20]: dr = L/N
```

```
# Create persistent dictionaries to track Hankel and Fourier results throughout.
H = {} # Hankel dict
F = {} # Fourier dict
r = np.linspace(dr/2, L-dr/2, N)
# 1D Grid for Hankel
H['r'] = r
# To decide on k values to use, we need to know the scales
# we'll require to evaluate on the *inverse* transform:
H['k'] = np.logspace(-0.5, 2.1, 2*N)  # k-space is rather arbitrary.
# 2D Grid for Fourier
F['x'] = np.arange(-N, N)*dr
F['rgrid'] = np.sqrt(np.add.outer(F['x']**2, F['x']**2))
F['fgrid'] = f(F['rgrid'])
```

Analytic Result

Utility Functions

```
[22]: def plot_comparison(x, y, ylabel, comp_ylim=None, F=F, H=H, **subplot_kw):
    fnc = globals()[y]
    subplot_kw.update({"xscale":'log'})
    fig, ax = plt.subplots(
        2,1, sharex=True, subplot_kw=subplot_kw,
        figsize=(12, 7), gridspec_kw={"hspace":0.07})
    ax[0].plot(H[x], fnc(H[x]), linewidth=2, label="Analytic", color="C2")
    ax[0].plot(H[x], H[y],linewidth=2, ls="--", label="Hankel")
    ax[0].plot(F[x], F[y],linewidth=2, ls="--", label="Fourier")
    ax[0].legend(fontsize=14)
    ax[0].est_ylabel(ylabel, fontsize=15)
```

(continues on next page)

(continued from previous page)

Example 1: Compute Laplacian

1. Forward Transform

a. Hankel

```
[195]: # Compute Hankel transform
H['fhat'] = ht.transform(f, H['k'], ret_err=False) # Return the transform of f_
at k.
```

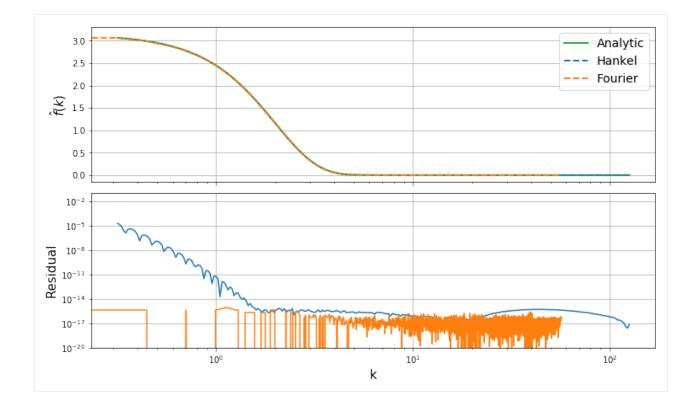

b. Fourier

```
[196]: F['fhat_grid'], F['kgrid'], F['k'], F['fhat'] = ft2d(F['fgrid'], 2*L)
```

c. Comparison

Comparing the results of the Hankel and Fourier Transforms, we have

```
[197]: plot_comparison('k', 'fhat', "$\hat{f}(k)$", comp_ylim=(1e-20, 1e-1))
```

2. Inverse Transform

a. Hankel

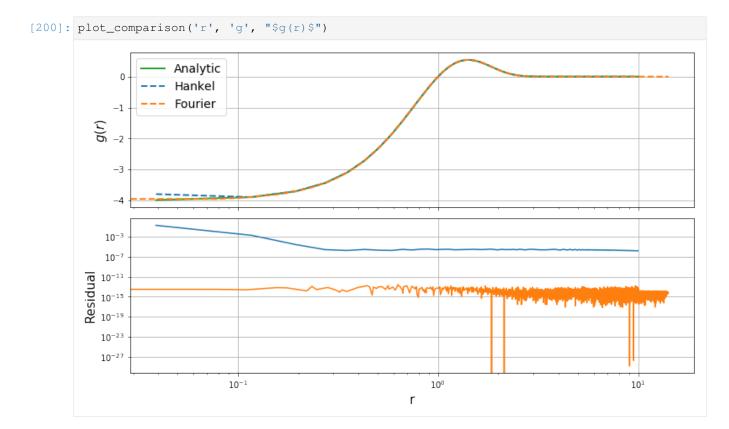

[198]: # Build a spline to approximate ghat

```
H['ghat'] = -H['k']**2 * H['fhat']
# We can build the spline carefully since we know something about the function
spl = spline(np.log(H['k'][H['ghat']!=0]), np.log(np.abs(H['ghat'][H['ghat']!=0])), _____k=2)
_fnc = lambda k: np.where(k < 1e2, -np.exp(spl(np.log(k))), 0)
# Do the transform
H['g'] = ht.transform(_fnc, H['r'], ret_err=False, inverse=True)</pre>
```

b. Fourier

```
[199]: F['ghat'] = -F['kgrid']**2 *F['fhat_grid']
F['ggrid'], _, F['r'], F['g'] = ft2d(F['ghat'], 2*L, inverse=True)
```

c. Compare

Example 2: Invert Laplacian

The Laplacian transformation can be inverted by following a similar set of steps in reverse:

1. Compute the Forward Transform

$$\mathcal{H}[g(r)] = \hat{g}(k)$$

2. Differentiate in Spectral space

$$\hat{f}(k) = -\frac{1}{k^2}\hat{g}(k)$$

3. Compute the Inverse Transform

$$f(r) = \mathcal{H}^{-1}[\hat{f}(k)]$$

1. Forward Transform

a. Hankel

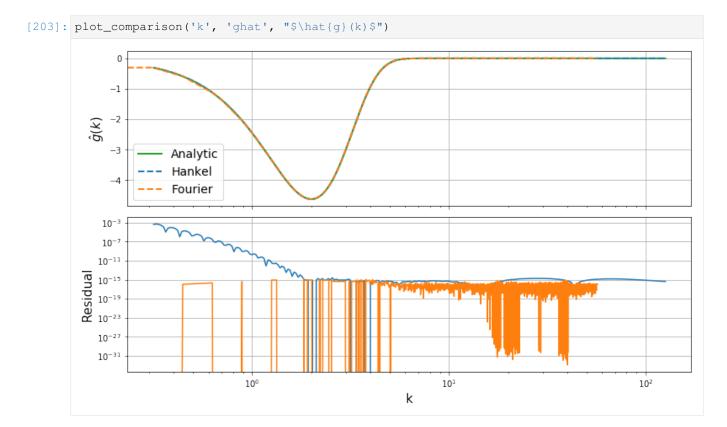

```
[201]: H['ghat'] = ht.transform(g, H['k'], ret_err=False) # Return the transform of g_ <math>\rightarrow at \ k.
```

b. Fourier

[202]: # Compute Fourier Transform

F['ghat_grid'], _, _, F['ghat'] = ft2d(g(F['rgrid']), 2*L)

c. Compare

2. Inverse Transform

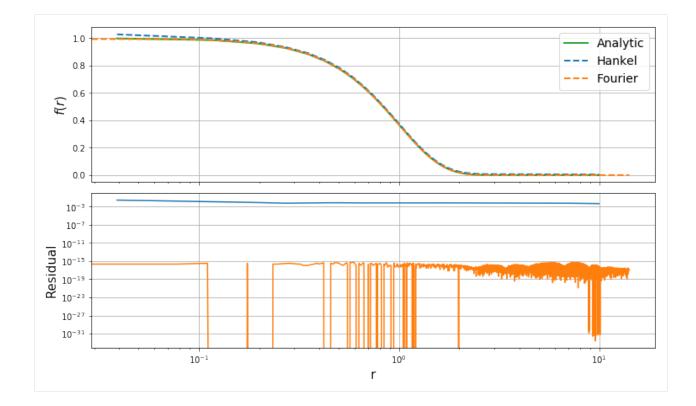

a. Hankel

```
[204]: # Interpolate onto a spline
spl_inv = spline(H['k'], -H['ghat']/H['k']**2)
H['f'] = ht.transform(spl_inv, H['r'], ret_err=False, inverse=True)
```

b. Fourier

c. Compare

```
[206]: plot_comparison('r', 'f', "$f(r)$")
```

Example 3: Laplacian in 3D

Generalising the previous calculations slightly, we can perform the Laplacian transformation in 3D using the Hankel transform correspondin to a circularly-symmetric FT in 3-dimensions (see the "Getting Started" notebook for details). Analytically, we obtain

$$\hat{f}(k) = \pi^{3/2} e^{-k^2/4}$$
$$\hat{g}(k) = -k^2 \pi^{3/2} e^{-k^2/4}$$
$$g(r) = 4e^{-r^2} (r^2 - 1.5)$$

Analytic Functions

```
[6]: g3 = lambda r: 4.0*np.exp(-r**2)*(r**2 - 1.5)
fhat3 = lambda k : np.pi**(3./2) * np.exp(-k**2/4)
ghat3 = lambda k : -k**2 * fhat3(k)
```

Grid Setup

```
[2]: L = 10.0 # Size of box for transform
N = 128 # Grid size
b0 = 1.0
```

```
[7]: # Create the Hankel Transform object
```

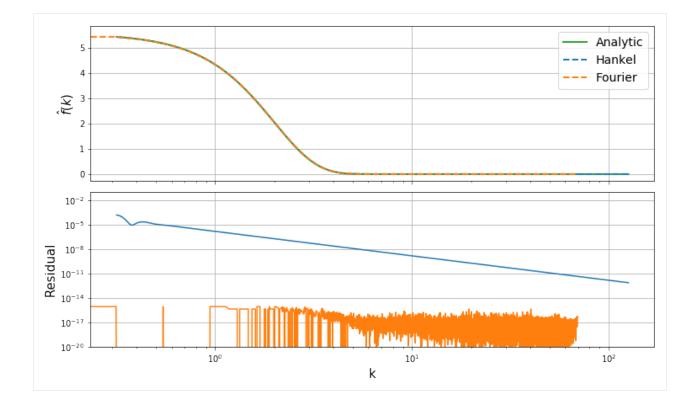

```
ht = SymmetricFourierTransform(ndim=3, h=0.005)
```

```
[11]: dr = L/N
```

Forward

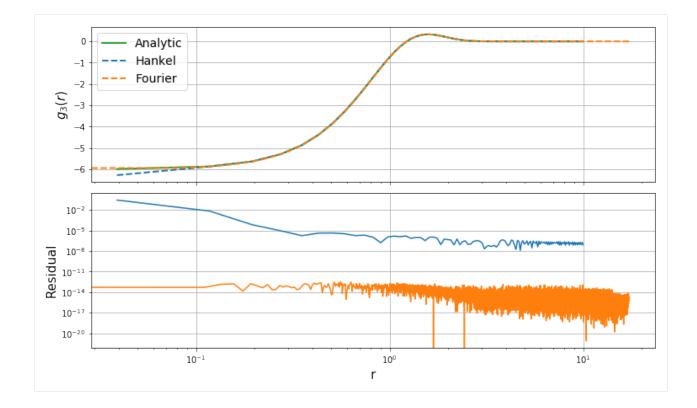

```
[24]: H3['fhat3'] = ht.transform(f, H3['k'], ret_err=False)
F3['fhat_grid'], F3['kgrid'], F3['k'], F3['fhat3'] = ft2d(F3['fgrid'], 2*L)
```

[25]: plot_comparison('k', 'fhat3', "\$\hat{f}(k)\$", comp_ylim=(1e-20, 1e-1), F=F3, H=H3)

Backward

```
[28]: # Build a spline to approximate ghat
H3['ghat3'] = -H3['k']**2 * H3['fhat3']
# We can build the spline carefully since we know something about the function
spl = spline(np.log(H3['k'][H3['ghat3']!=0]), np.log(np.abs(H3['ghat3'][H3['ghat3']!
...=0])), k=2)
_fnc = lambda k: np.where(k < le2, -np.exp(spl(np.log(k))), 0)
# Do the transform
H3['g3'] = ht.transform(_fnc, H3['r'], ret_err=False, inverse=True)
[34]: F3['ghat3'] = -F3['kgrid']**2 *F3['fhat_grid']
F3['ggrid'], _, F3['r'], F3['g3'] = ft2d(F3['ghat3'], 2*L, inverse=True)
[35]: plot_comparison('r', 'g3', "$g_3(r)$", H=H3, F=F3)
```

n-Dimensional Transform

Generalising again, the n-dimensionsal transform functions can be written

$$\hat{f}(k) = \pi^{n/2} e^{-k^2/4}$$
$$\hat{g}(k) = -k^2 \pi^{n/2} e^{-k^2/4}$$
$$g(r) = 2e^{-r^2} (2r^2 - n)$$

In this section, we show the performance (both in speed and accuracy) of the Hankel transform algorithm to produce g(r) for arbitrary dimensions. We do not use the FT-method in this section as its memory consumption obviously scales as N^n , and its CPU performance as $nN^n \log N$.

```
[40]: gn = lambda r, n: 2* np.exp(-r**2) * (2*r**2 - n)
[37]: def gn_hankel(r, n, h=0.005):
    ht = SymmetricFourierTransform(ndim=n, h=h)
    k = np.logspace(-0.5, 2.1, 2*N)
    fhat = ht.transform(f, k, ret_err=False)
    ghat = -k**2 * fhat
    # We can build the spline carefully since we know something about the function
    spl = spline(np.log(k[ghat!=0]), np.log(np.abs(ghat[ghat!=0])), k=2)
    _fnc = lambda k: np.where(k < 1e2, -np.exp(spl(np.log(k))), 0)
    # Do the transform
    return ht.transform(_fnc, r, ret_err=False, inverse=True)</pre>
```

Let's get the timing information for each calculation:

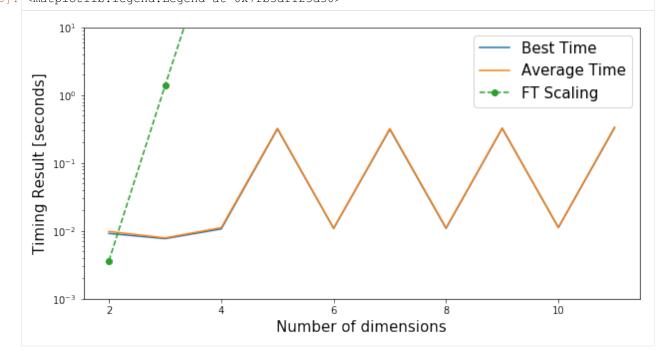

```
[82]: times = [0]*len(ns)
for i, n in enumerate(ns):
   times[i] = %timeit -o gn_hankel(rs, n);

9.86 ms ± 489 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
7.91 ms ± 145 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
11.2 ms ± 507 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
327 ms ± 6.09 ms per loop (mean ± std. dev. of 7 runs, 1 loop each)
11 ms ± 90.1 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
324 ms ± 4.82 ms per loop (mean ± std. dev. of 7 runs, 1 loop each)
11.1 ms ± 104 µs per loop (mean ± std. dev. of 7 runs, 1 loop each)
329 ms ± 2.01 ms per loop (mean ± std. dev. of 7 runs, 1 loop each)
11.3 ms ± 34 µs per loop (mean ± std. dev. of 7 runs, 100 loops each)
339 ms ± 8.27 ms per loop (mean ± std. dev. of 7 runs, 1 loop each)
```

Here's a plot of the timing results. Note how odd-dimensions result in longer run-times, as the Bessel functions are 1/2-order, which requires more sophisticated methods from mpmath to calculate. There is no overall progression of

the computational load with dimensionality, however.

This is in contrast to a FT approach, which scales as N^n , shown in green.

6.3 Changelog

6.3.1 v1.0.0

Enhancements

- Limit calculation for k=0 provided (resulted in nan before)
- Alternative hankel kernel now selectable: sqrt(x) * J(nu, x)
- Caching of series factors for faster calculations
- Various infrastructure upgrades (setuptools_scm, pre-commit, black)

Bugfixes

• Saver calculation of xrange_approx

Deprecations

• Methods G and deltaG now named final_term_amplitude and slope_of_last_term.

6.3.2 0.3.9

Version corresponding to JOSS paper release.

Bugfixes

• Fixed SymmetricFourierTransform default N to be dynamic, like HankelTransform.

6.3.3 v0.3.8 [08 Jan 2019]

Enhancements

- Swapped to pytest from nose for all testing
- Removed warnings of overflow for cosh and sinh functions
- Improved documentation in many areas.
- Swapped out default 3.2/h for pi/h, which sounds way cooler :-)

Bugfixes

- Fixed an error in tests such that the wrong analytic function was being tested.
- Removed a check for deltaG in get_h, which sometimes fails spectacularly.

6.3.4 v0.3.7 [11 Dec 2018]

Bugfixes

• Fixed issue in Py3 in which dim=2 would not run the fast function (thanks @MuellerSeb)

6.3.5 v0.3.6 [6 Aug 2018]

Enhancements

• Added support for transforms with nu=-0.5 (thanks @MuellerSeb)

6.3.6 v0.3.5 [8 Dec 2017]

Bugfixes

• Fixed Python 3 support from v0.3.4

6.3.7 v0.3.4 [28 July 2017]

Features

• Added get_h function to aide in determining optimal h value for a given transformation.

Enhancements

- Added _get_series method to quickly retrieve the summed series for the integration.
- Two updated notebook examples.

Bugfixes

• Moved setting of N to avoid error.

6.3.8 v0.3.3 [28 July 2017]

Features

• Some additional tools to determine accuracy - quick calculation of last term in sum, and evaluated range.

Enhancements

• Default setting of N=3.2/h, which is the maximum possible N that should be chosen, as above this, the series truncates due to the double-exponential convergence to the roots of the Bessel function.

Bugfixes

• Fixed error in cumulative sum when k is not scalar.

6.3.9 v0.3.2 [12 July 2017]

Enhancements

- Documentation! See it at https://hankel.readthedocs.io
- Two new jupyter notebook demos (find them in the docs) by @francispoulin

Bugfixes

- Fixed relative import in Python 3 (tests now passing), thanks to @louity
- Fixed docstring of SymmetricFourierTransform to have correct Fourier convention equation
- Fixed bug in choosing alternative conventions in which the fourier-dual variable was unchanged.

6.3.10 v0.3.1 [5 Jan 2017]

Bugfixes

• Fixed normalisation for inverse transform in SymmetricFourierTransform.

Features

• Ability to set Fourier conventions arbitrarily in SymmetricFourierTransform.

6.3.11 v0.3.0 [4 Jan 2017]

Features

- New class *SymmetricFourierTransform* which makes it incredibly easy to do arbitrary *n*-dimensional fourier transforms when the function is radially symmetric (includes inverse transform).
- Addition of *integrate* method to base class to perform Hankel-type integrals, which were previously handled by the *transform* method. This latter method is now used for actual Hankel transforms.
- Documentation!

Enhancements

- Addition of many tests against known integrals.
- Continuous integration
- Restructuring of package for further flexibility in the future.
- Quicker zero-finding of 1/2-order bessel functions.
- This changelog.
- Some notebooks in the devel/ directory which show how various integrals/transforms behave under different choices of integration steps.

6.3.12 v0.2.2 [29 April 2016]

Enhancements

- Compatibility with Python 3 (thanks to @diazona)
- Can now use with array-value functions (thanks to @diazona)

6.3.13 v0.2.1 [18 Feb 2016]

Bugfixes

• Fixed pip install by changing readme -> README

Enhancements

• updated docs to show dependence on mpmath

6.3.14 v0.2.0 [10 Sep 2014]

Features

• Non-integer orders supported through mpmath.

6.3.15 v0.1.0

• First working version. Only integer orders (and 1/2) supported.

6.4 Authors

Steven Murray: @steven-murray

6.4.1 Contributors

- Francis Poulin @francispoulin
- Sebastian Mueller @MuellerSeb
- # .. highlight :: shell

6.5 Contributing

Contributions are welcome, and they are greatly appreciated! Every little bit helps, and credit will always be given. You can contribute in many ways:

6.5.1 Types of Contributions

Report Bugs

Report bugs by opening a new issue.

If you are reporting a bug, please include:

- Your operating system name and version.
- Any details about your local setup that might be helpful in troubleshooting.
- Detailed steps to reproduce the bug.

Fix Bugs

Look through the GitHub issues for bugs. Anything tagged with "bug" and "help wanted" is open to whoever wants to implement it.

Implement Features

Look through the GitHub issues for features. Anything tagged with "enhancement" and "help wanted" is open to whoever wants to implement it.

Write Documentation

hankel could always use more documentation, whether as part of the official hankel docs, in docstrings, or even on the web in blog posts, articles, and such.

In particular, if you have used hankel in a novel way, please consider submitting a script or Jupyter notebook as "demo" documentation.

Submit Feedback

The best way to send feedback is to file an issue.

If you are proposing a feature:

- Explain in detail how it would work.
- Keep the scope as narrow as possible, to make it easier to implement.
- Remember that this is a volunteer-driven project, and that contributions are welcome :-)

6.5.2 Get Started!

Ready to contribute? Here's how to set up hankel for local development.

- 1. Fork the *hankel* repo on GitHub.
- 2. Clone your fork locally:

\$ git clone git@github.com:your_name_here/hankel.git

3. Install your local copy into a virtualenv. Assuming you have virtualenvwrapper installed, this is how you set up your fork for local development:

```
$ mkvirtualenv hankel
$ cd hankel/
$ pip install -e .[dev]
```

Note the optional extra install of the development dependencies.

If you are using *conda*, setup your environment the usual way, i.e. conda create -n hankel before installing as above.

4. Create a branch for local development:

\$ git checkout -b name-of-your-bugfix-or-feature

Now you can make your changes locally.

5. When you're done making changes, check that your changes pass flake8 and the tests, including testing other Python versions with tox:

```
$ flake8 hankel tests
$ py.test
$ tox
```

To get flake8 and tox, just pip install them into your virtualenv.

6. Commit your changes and push your branch to GitHub:

```
$ git add .
$ git commit -m "Your detailed description of your changes."
$ git push origin name-of-your-bugfix-or-feature
```

7. Submit a pull request through the GitHub website.

6.5.3 Pull Request Guidelines

Before you submit a pull request, check that it meets these guidelines:

- 1. The pull request should include tests.
- 2. If the pull request adds functionality, the docs should be updated. Ensure your new functionality is documented in the relevant docstring (we use Numpy-style docstrings). If it is a significant feature, it will also be preferable to add a demo notebook to the docs/demos/directory.
- 3. If you implement an important new feature, consider adding the feature to the list in README.rst.
- 4. The pull request should work for Python 2.7, 3.5, 3.6, and 3.7. Check https://travis-ci.org/steven-murray/hankel/ pull_requests and make sure that the tests pass for all supported Python versions.

6.5.4 Tips

To run a subset of tests:

```
$ py.test tests.test_hankel
```

6.5.5 Deploying

A reminder for the maintainers on how to deploy. Make sure all your changes are committed (including an entry in HISTORY.rst). Then run:

```
$ bumpversion patch # possible: major / minor / patch
$ git push
$ git push --tags
```

Travis will then deploy to PyPI if tests pass.

6.6 API Documentation

General quadrature method for Hankel transformations.

Based on the algorithm provided in H. Ogata, A Numerical Integration Formula Based on the Bessel Functions, Publications of the Research Institute for Mathematical Sciences, vol. 41, no. 4, pp. 949-970, 2005.

6.6.1 Classes

HankelTransform([nu, N, h, alt])	The basis of the Hankel Transformation algorithm by Ogata 2005.
SymmetricFourierTransform([ndim, a, b, N,	Fourier Transform of a radially symmetric function in
])	arbitrary dimensions.

6.6.2 Functions

get_h(f, nu[, K, cls, hstart, hdecrement,])	Determine the largest value of h which gives a con-
	verged solution.

class hankel.**HankelTransform** (*nu=0*, *N=None*, *h=0.05*, *alt=False*) The basis of the Hankel Transformation algorithm by Ogata 2005.

This algorithm is used to solve the equation $\int_0^\infty f(x) J_\nu(x) dx$ where $J_\nu(x)$ is a Bessel function of the first kind of order ν , and f(x) is an arbitrary (slowly-decaying) function.

The algorithm is presented in H. Ogata, A Numerical Integration Formula Based on the Bessel Functions, Publications of the Research Institute for Mathematical Sciences, vol. 41, no. 4, pp. 949-970, 2005.

This class provides a method for directly performing this integration, and also for doing a Hankel Transform.

Parameters

• nu (scalar, optional) – The order of the bessel function (of the first kind) J_nu(x)

- N (int, optional, default = pi/h) The number of nodes in the calculation. Generally this must increase for a smaller value of the step-size h. Default value is based on where the series will truncate according to the double-exponential convergence to the roots of the Bessel function.
- **h** (float, optional) The step-size of the integration.
- **alt** (*bool*, *optional*) Whether to use the alternative definition of the hankel transform. should be used. Default: False

classmethod G(f, h, k=None, *args, **kwargs)
Alias of final_term_amplitude().

Deprecated since version Deprecated: as of v1. Will be removed in v1.2.

classmethod deltaG(f, h, *args, **kwargs) Alias of slope_of_last_term().

Deprecated since version Deprecated: as of v1. Will be removed in v1.2.

classmethod final_term_amplitude (*f*, *h*, *k=None*, **args*, ***kwargs*) Get the amplitude of the last term in cumulative sum.

The absolute value of the non-oscillatory component of the summed series' last term, up to a scaling constant. This can be used to get the sign of the slope of the amplitude with h.

Parameters

- **f** (callable) The function to integrate/transform
- h (float) The resolution parameter of the hankel integration
- **k** (float or array-like, optional) The scale at which to evaluate the transform. If None, assume an integral.

Returns The value of G, the amplitude of the final term in the series' sum.

Return type float

integrate (self, f, ret_err=True, ret_cumsum=False)

Do the Hankel-type integral of the function f.

This is *not* the Hankel transform, but rather the simplified integral, $\int_0^\infty f(x) J_\nu(x) dx$, equivalent to the transform of f(r)/r at k=1.

Parameters

- **f** (*callable*) A function of one variable, representing f(x)
- **ret_err** (boolean, optional, default = True) Whether to return the estimated error
- **ret_cumsum** (boolean, optional, default = False) Whether to return the cumulative sum

Returns

- **ret** (*float*) The Hankel integral of f(x).
- **err** (*float*) The estimated error of the approximate integral. It is merely the last term in the sum. Only returned if *ret_err=True*.
- **cumsum** (*array-like*) The total cumulative sum, for which the last term is itself the integral. One can use this to check whether the integral is converging. Only returned if *ret_cumsum=True*

See also:

transform() The Hankel transform (this function calls transform() with k=1 and f(x) = f(x)/x.

property nu

Order of the hankel transform.

classmethod slope_of_last_term(f, h, *args, **kwargs)

Get the slope (up to a constant) of the last term of the series with h.

Parameters

- **f** (*callable*) The function to integrate/transform
- **h** (*float*) The resolution parameter of the hankel integration
- **Other Parameters args, kwargs** All other parameters are passed through to final_term_amplitude().

Returns The derivative of the last term of the series with h.

Return type float

transform (*self*, *f*, *k*=1, *ret_err=True*, *ret_cumsum=False*, *inverse=False*) Do the Hankel-transform of the function f.

Parameters

- **f** (callable) A function of one variable, representing f(x)
- **ret_err** (boolean, optional, default = True) Whether to return the estimated error
- **ret_cumsum** (boolean, optional, default = False) Whether to return the cumulative sum

Returns

- ret (array-like) The Hankel-transform of f(x) at the provided k. If k is scalar, then this will be scalar.
- **err** (*array-like*) The estimated error of the approximate integral, at every *k*. It is merely the last term in the sum. Only returned if *ret_err=True*.
- **cumsum** (*array-like*) The total cumulative sum, for which the last term is itself the transform. One can use this to check whether the integral is converging. Only returned if *ret_cumsum=True*

Notes

The Hankel transform is defined as

$$F(k) = \int_0^\infty rf(r)J_\nu(kr)dr.$$

Or in the alternative case with alt=True:

$$F(k) = \int_0^\infty f(r)\sqrt{kr}J_\nu(kr)dr.$$

The inverse transform is identical (swapping k and r of course).

xrange (*self*, k=1)

Tuple giving $(\min, \max) x$ value evaluated by f(x).

```
Parameters k (array-like, optional) – Scales for the transformation. Leave as 1 for an integral.
```

See also:

xrange_approx() An approximate version of this method which is a classmethod.

```
classmethod xrange_approx(h, nu, k=1)
```

Tuple giving approximate (min,max) x value evaluated by f(x/k).

Operates under the assumption that N = 3.2/h.

Parameters

- h (float) The resolution parameter of the Hankel integration
- **nu** (float) Order of the integration/transform
- **k** (array-like, optional) Scales for the transformation. Leave as 1 for an integral.

See also:

xrange () The actual x-range under a given choice of parameters.

class hankel.**SymmetricFourierTransform** (*ndim=2*, *a=1*, *b=1*, *N=None*, *h=0.05*, *alt=True*) Fourier Transform of a radially symmetric function in arbitrary dimensions.

Parameters

- ndim (*int*) Number of dimensions the transform is in.
- **b** (*a*,) This pair of values defines the Fourier convention used (see Notes below for details)
- **N** (*int*, *optional*) The number of nodes in the calculation. Generally this must increase for a smaller value of the step-size h.
- **h**(float, optional) The step-size of the integration.
- **alt** (*bool*, *optional*) State if the alternative definition of the hankel transform should be used. Default: False

Notes

We allow for arbitrary Fourier convention, according to the scheme in http://mathworld.wolfram.com/ FourierTransform.html. That is, we define the forward and inverse *n*-dimensional transforms respectively as

$$F(k) = \sqrt{\frac{|b|}{(2\pi)^{1-a}}}^n \int f(r)e^{ib\mathbf{k}\cdot\mathbf{r}}d^n\mathbf{r}$$

and

$$f(r) = \sqrt{\frac{|b|}{(2\pi)^{1+a}}}^n \int F(k)e^{-ib\mathbf{k}\cdot\mathbf{r}}d^n\mathbf{k}.$$

By default, we set both a and b to 1, so that the forward transform has a normalisation of unity.

In this general sense, the forward and inverse Hankel transforms are respectively

$$F(k) = \sqrt{\frac{|b|}{(2\pi)^{1-a}}}^n \frac{(2\pi)^{n/2}}{(bk)^{n/2-1}} \int_0^\infty r^{n/2-1} f(r) J_{n/2-1}(bkr) r dr$$

and

$$f(r) = \sqrt{\frac{|b|}{(2\pi)^{1+a}}} \frac{(2\pi)^{n/2}}{(br)^{n/2-1}} \int_0^\infty k^{n/2-1} f(k) J_{n/2-1}(bkr) k dk.$$

classmethod G(f, h, k=None, ndim=2)

Info about the last term in the series.

Deprecated since version Deprecated: as of v1. Will be removed in v1.2.

```
classmethod final_term_amplitude (f, h, k=None, ndim=2)
```

Get the amplitude of the last term in cumulative sum.

The absolute value of the non-oscillatory component of the summed series' last term, up to a scaling constant. This can be used to get the sign of the slope of the amplitude with h.

Parameters

- **f** (callable) The function to integrate/transform
- **h** (*float*) The resolution parameter of the hankel integration
- **k** (float or array-like, optional) The scale at which to evaluate the transform. If None, assume an integral.
- ndim (float) The number of dimensions of the transform

Returns The amplitude of the final term in the sum.

Return type float

classmethod xrange_approx (h, ndim, k=1)

Tuple giving approximate (min,max) x value evaluated by f(x/k).

Operates under the assumption that N = pi/h.

Parameters

- h (float) The resolution parameter of the Hankel integration
- **ndim** (*float*) Number of dimensions of the transform.
- **k** (array-like, optional) Scales for the transformation. Leave as 1 for an integral.

See also:

xrange () the actual x-range under a given choice of parameters.

hankel.get_h (f, nu, K=None, cls=None, hstart=0.05, hdecrement=2, atol=0.001, rtol=0.001, maxiter=15, inverse=False)

Determine the largest value of h which gives a converged solution.

Parameters

- **f** (*callable*) The function to be integrated/transformed.
- nu (float) Either the order of the transformation, or the number of dimensions (if *cls* is a SymmetricFourierTransform)

- **K** (float or array-like, optional) The scale(s) of the transformation. If None, assumes an integration over f(x)J_nu(x) is desired. It is recommended to use a down-sampled K for this routine for efficiency. Often a min/max is enough.
- **cls** (*HankelTransform* subclass, optional) Either *HankelTransform* or a subclass, specifying the type of transformation to do on *f*.
- hstart (float, optional) The starting value of h.
- hdecrement (float, optional) How much to divide h by on each iteration.
- **rtol** (*atol*,) The tolerance parameters, passed to *np.isclose*, defining the stopping condition.
- maxiter (int, optional) Maximum number of iterations to perform.
- **inverse** (bool, optional) Whether to treat as an inverse transformation.

Returns

- **h** (*float*) The h value at which the solution converges.
- **res** (*scalar or tuple*) The value of the integral/transformation using the returned h if a transformation, returns results at K.
- N (*int*) The number of nodes necessary in the final calculation. While each iteration uses N=pi/h, the returned N checks whether nodes are numerically zero above some threshold.

Notes

This function is not completely general. The function f is assumed to be reasonably smooth and non-oscillatory.

The idea is to use successively smaller values of h, with N=pi/h on each iteration, until the result between iterations becomes stable.
